- PyPy and Go gc approaches

CPython reference counting

Reference Counting

For each object, use a counter to keep the number of references to the object

When the reference count is increased?

- assignment operator
- argument passing
- appending an object to a list
- ...

When the reference count is decreased?

- reference goes out of scope (function return)
- ...

sys.getrefcount

```
foo = []
# 2 references, 1 from the foo var and 1 from getrefcount
sys.getrefcount(foo)

    (a):
    # 4 references
    # from the foo var, function argument,
    # getrefcount and Python's function stack
    sys.getrefcount(a)

bar(foo)
# 2 references, the function scope is destroyed
sys.getrefcount(foo)
```

Quick Quiz #1: sys.getrefcount oddities

If you run the following snippet with CPython 3.7.3 in a REPL

```
import sys
a = 1
sys.getrefcount(a)
```

you'll get 118

Can you figure out why this happens?

Quick Quiz #1: sys.getrefcount oddities

If you run the following snippet with CPython 3.7.3 in a REPL

```
import sys
a = 1
sys.getrefcount(a)
```

you'll get 118

Can you figure out why this happens?

answer

CPython the number from -5 to 256 (including) to save memory and optimize performance. Same thing goes for strings with just one character.

refcount - PyObject

In CPython, each object stores the number of references to it in the ob_refcnt field

```
typedef struct _object {
    _PyObject_HEAD_EXTRA
    Py_ssize_t ob_refcnt;
    struct _typeobject *ob_type;
} PyObject;
```

refcount - Py_INCREF and Py_DECREF

How ob_refcnt is incremented and decremented in CPython?

```
static inline void _Py_INCREF(PyObject *op)
{
    _Py_INC_REFTOTAL;
    op->ob_refcnt++;
}
#define Py_INCREF(op) _Py_INCREF(_PyObject_CAST(op))
```

Tinkering with the Python C API

The Application Programmer's Interface to Python gives C programmers access to the Python interpreter

The most common use of the Python C API is to write extension modules for specific purposes

We'll leverage the Python C API to demostrate how a leak can occur if the reference count doesn't hit 0

A leaking extension

Correct and incorrect use of pobj reference

```
static PyObject *
cPyRefs_good_incref(PyObject *pModule, PyObject *pObj)
{
    PySys_WriteStdout("cPyRefs_good_incref\n");
    Py_INCREF(pObj);
    // use pObj

    Py_DECREF(pObj);
    Py_RETURN_NONE;
}
```

```
static PyObject *
cPyRefs_bad_incref(PyObject *pModule, PyObject *pObj)
{
    PySys_WriteStdout("cPyRefs_bad_incref\n");
    Py_INCREF(pObj);

    // use pObj

    Py_RETURN_NONE;
}
```

Demo time!

The good, the bad and the ugly about reference counting

Good

- easy to implement
- when refcount hits 0, objs are immediately deleted

Bad

- · space overhead
- execution overhead
 - o extra check whenever an object gets allocated, referenced, or dereferenced
- unbounded latency
 - o for large and convoluted heaps
- memory fragmentation

Ugly

- not thread safe
- doesn't detect cycles

The ugly 1/2: not thread safe

What if two threads concurrently decrease an object reference counter?

```
Suppose refcnt == 2
```

Thread 1:

```
CPU register <- refcnt
CPU register -= 1
refcnt <- CPU register
```

Thread 2:

```
CPU register <- refcnt
CPU register -= 1
refcnt <- CPU register
```

These operations are not atomic, so there's a race condition...

refent may end up with a value of 0 or 1!!!

If refent turns out to be 1, we may experience a **memory leak** :-(

Quick Quiz #2: Concurrently increasing refent

What happens if two threads try to concurrently increase the same refent?

Quick Quiz #2: Concurrently increasing refent

What happens if two threads try to concurrently increase the same refent?

answer

Even worse than before!

We have again a race condition: the ref counter may be increased just by 1. Since it will permanently be lower than its real value, the object may be collected when it is still actively referenced.

Therefore, we may end up **referencing memory already freed** and all sorts of (bad) things can happen.

Solution: the Python's *infamous* GIL

Global Interpreter Lock

One single lock to be held to interact with the Python interpreter in any way e.g. run bytecode, allocate memory, call any C API and so on...

Pros

- easy to get right
- no deadlocks possible
- good I/O bound multithreads performance

Cons

bad CPU bound multithreads performance

Global Interpreter Lock

One single lock to be held to interact with the Python interpreter in any way

e.g. run bytecode, allocate memory, call any C API and so on...

Pros

- easy to get right
- no deadlocks possible
- good I/O bound multithreads performance

Cons

bad CPU bound multithreads performance

But please, don't hold a grudge against the GIL...

"The design decision of the GIL is one of the things that made Python as popular as it is today"

- Larry Hastings -

The ugly 2/2: cyclical references

Reference cycles can only occur in container objects (lists, dicts, classes, tuples)

Here an example:

```
obj_1, obj_2 = {}, {}
obj_1['next'], obj_2['next'] = obj_2, obj_1
```

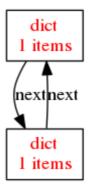

The ugly 2/2: cyclical references

Reference cycles can only occur in container objects (lists, dicts, classes, tuples)

Here an example:

```
obj_1, obj_2 = {}, {}
obj_1['next'], obj_2['next'] = obj_2, obj_1
```

objgraph module confirms the we are dealing with a cyclic reference:

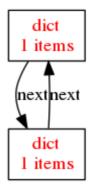

The ugly 2/2: cyclical references

Reference cycles can only occur in container objects (lists, dicts, classes, tuples)

Here an example:

```
obj_1, obj_2 = {}, {}
obj_1['next'], obj_2['next'] = obj_2, obj_1
```

objgraph module confirms the we are dealing with a cyclic reference:

How to solve this?

CPython generational garbage collection

CPython adds to the reference counting, another garbage collector to deal with cyclic references

That additional GC is a form of *tracing garbage collection*. As such, it consists of threee phases:

- 1. Scan
- 2. Mark
- 3. Sweep

CPython adds to the reference counting, another garbage collector to deal with cyclic references

That additional GC is a form of *tracing garbage collection*. As such, it consists of threee phases:

- 1. Scan
- 2. Mark
- 3. Sweep

In a nutshell: the gc **scan** the entire heap to **mark** reachable objects, then **sweep** away the unreachable ones

CPython adds to the reference counting, another garbage collector to deal with cyclic references

That additional GC is a form of *tracing garbage collection*. As such, it consists of threee phases:

- 1. Scan
- 2. Mark
- 3. Sweep

In a nutshell: the gc **scan** the entire heap to **mark** reachable objects, then **sweep** away the unreachable ones

These are costly operations, but CPython manges to improve the overall performance using a *heuristic* approach

CPython adds to the reference counting, another garbage collector to deal with cyclic references

That additional GC is a form of *tracing garbage collection*. As such, it consists of threee phases:

- 1. Scan
- 2. Mark
- 3. Sweep

In a nutshell: the gc **scan** the entire heap to **mark** reachable objects, then **sweep** away the unreachable ones

These are costly operations, but CPython manges to improve the overall performance using a *heuristic* approach

The **generational hypothesis** says that the most recently created objects are also those most likely to become unreachable quickly

Short-lived objects allocation

We define the **age** of an object as the number of times it survived a garbage collection cycle

Short-lived objects allocation

We define the **age** of an object as the number of times it survived a garbage collection cycle

Does the generational hypotesis holds true in Python?

```
# allocates temporary floats
avg = (a + b + c)/3

# allocates a temporary iterator for sequence
[x for x in sequence]

# allocates many temporary strings
python.replace('CPython', 'PyPy').replace('PyPy', 'Jython')
    .replace('Jython', 'IronPython').replace('IronPython', 'PythonNet')

# and so on
```

Short-lived objects allocation

We define the **age** of an object as the number of times it survived a garbage collection cycle

Does the generational hypotesis holds true in Python?

```
# allocates temporary floats
avg = (a + b + c)/3

# allocates a temporary iterator for sequence
[x for x in sequence]

# allocates many temporary strings
python.replace('CPython', 'PyPy').replace('PyPy', 'Jython')
.replace('Jython', 'IronPython').replace('IronPython', 'PythonNet')

# and so on
```

Take home message

We can separate objects by their age, enqueing them in separate lists (**generations**). Then, it is convenient to collect younger generations frequently than older ones.

CPython generational gc

CPython keeps three lists of every (**container**) object allocated as a program is run:

- generation 0
- generation 1
- generation 2

Younger objects are stored in generation 0 and they are *promoted* to the older generation if they survive a garbage collection cycle.

Generational garbage collection in action

gc module

We can use the ctypes foreign function library to expose ob_refcnt for *lost* Python objects

```
import ctypes
import qc
# disable garbage collection
gc.disable()
# use ctypes to map PyObject internal struct
class PyObject(ctypes.Structure):
   fields = [('ob refcnt', ctypes.c ssize t)]
# create a cyclical reference
obj_1, obj_2 = {}, {}
obj 1['next'], obj 2['next'] = obj 2, obj 1
# save objs addresses
obj_1_addr, obj_2_addr = id(obj_1), id(obj_2)
del obj 1, obj 2
# prove that refcounts are not 0 due to cyclical reference
print(f'obj 1 refcnt: '
    '{PyObject.from address(obj 1 addr).ob refcnt}')
print(f'obj 2 refcnt:
    '{PyObject.from_address(obj_2_addr).ob_refcnt}')
```

gc module

Executing the script with CPython 3.7.3, we can see how the generational gc collects the two objects

```
before gc collect
obj_1 refcount: 1
obj_2 refcount: 1
gc start {'generation': 2, 'collected': 0, 'uncollectable': 0}
gc stop {'generation': 2, 'collected': 2, 'uncollectable': 0}
after gc collect
obj_1 refcount: 0
obj_2 refcount: 0
```

Quick Quiz #3: PyObject and ctypes

Consider again the PyObject structure

```
#define _PyObject_HEAD_EXTRA
    struct _object *_ob_next;
    struct _object *_ob_prev;

typedef struct _object {
    _PyObject_HEAD_EXTRA
    Py_ssize_t ob_refcnt;
    struct _typeobject *ob_type;
} PyObject;
```

and the definition of our ctypes class PyObject

```
class PyObject(ctypes.Structure):
    _fields_ = [('ob_refcnt', ctypes.c_ssize_t)]
```

Can you figure out why _PyObject_HEAD_EXTRA is not mapped with ctypes?

Quick Quiz #3: PyObject and ctypes

Consider again the PyObject structure

```
#define _PyObject_HEAD_EXTRA
    struct _object *_ob_next;
    struct _object *_ob_prev;

typedef struct _object {
    _PyObject_HEAD_EXTRA
    Py_ssize_t ob_refcnt;
    struct _typeobject *ob_type;
} PyObject;
```

and the definition of our ctypes class PyObject

```
class PyObject(ctypes.Structure):
    _fields_ = [('ob_refcnt', ctypes.c_ssize_t)]
```

Can you figure out why _PyObject_HEAD_EXTRA is not mapped with ctypes?

answer

Because _PyObject_HEAD_EXTRA expand to nothing if the macro Py_TRACE_REFS is not defined!

CPython generational gc internals

GC container objects

Container objects that should be tracked by generational gc are identified by a flag

```
/* Objects support garbage collection (see objimp.h) */
#define Py_TPFLAGS_HAVE_GC (1UL << 14)</pre>
```

a C macro is defined to help test for the presence of the flag

An example of a GC container object

As an example, consider the defaultdict type from collections module

from Modules/_collectionsmodule.c:

GC internal structs: PyGC_Head

GC information is stored on top of every PyObject

Specifically, every gc tracked object is linked in a doubly-linked list through a struct PyGC_Head

```
/* GC information is stored BEFORE the object structure. */
typedef struct {
    // Pointer to next object in the list.
    // 0 means the object is not tracked
    uintptr_t _gc_next;

    // Pointer to previous object in the list.
    // Lowest two bits are used for flags documented later.
    uintptr_t _gc_prev;
} PyGC_Head;
```

We can go from a PyObject * to a PyGC_Head * with the help of these two macros

```
/* Get an object's GC head */
#define AS_GC(o) ((PyGC_Head *)(o)-1)

/* Get the object given the GC head */
#define FROM_GC(g) ((PyObject *)(((PyGC_Head *)g)+1))
```

_gc_prev field

When not collecting, _gc_prev is to link container objects in a doubly linked list

Lowest two bits of _gc_prev are used for flags. The most important one is PREV_MASK_COLLECTING, which is set when the object is undergoing a collection and cleared once the cycle detection algorithm ends.

During a collection, _gc_prev is temporary used for storing gc_refs, that is the current value of ob_refcnt.

FIXME: move this

- gc_refs
 At the start of a collection, update_refs() copies the true refcount to
 gc_refs. subtract_refs() adjusts this value so that it equals the number of
 times an object is referenced directly from outside the generation being
 collected. This way, the true value of ob_refcnt won't be polluted by the
 generational gc.
- PREV_MASK_COLLECTING
 Objects in generation being collected are marked as PREV_MASK_COLLECTING in update_refs().

_gc_next field

_gc_next takes these values:

- 0
 The object is not tracked
- != 0
 Pointer to the next object in the GC list. Additionally, lowest bit is used temporary for NEXT_MASK_UNREACHABLE flag described below.
- NEXT_MASK_UNREACHABLE the object is marked as unreachable and so it is a candidate for deallocation

FIXME: move this

move_unreachable() then moves objects not reachable (whether directly or indirectly) from outside the generation into an "unreachable" set and set this flag.

Quick quiz #4:

Why CPython uses the same field <u>_gc_prev</u> both as a pointer and as a reference counter?

Quick quiz #4:

Why CPython uses the same field _gc_prev both as a pointer and as a reference counter?

answer

To reduce memory overhead: every single container object has a structure PyGCHead on top of it!

GC internal structs: gc_generation

Descriptor of a GC generation

```
struct gc_generation {
    PyGC_Head head;
    int threshold;
    int count;
};
```

- head
 all gc_generation structs are doubly-linked
- threshold garbage collection threshold
- count

for generation 0: difference between allocations and deallocations for older generations: count of collections completed

_PyRuntime.gc.generations[0].count

- is incremented in _PyObject_GC_Alloc
- decremented in PyObject_GC_Del

GC internal structs: gc_generations_stats

Struct that holds info about generations statistics

```
/* Running stats per generation */
struct gc_generation_stats {
    /* total number of collections */
    Py_ssize_t collections;
    /* total number of collected objects */
    Py_ssize_t collected;
    ...
};
```

CPython gives us the possibility to read these statistics

```
import gc
gc.disable()
gc.set_debug(gc.DEBUG_STATS)
gc.collect()
```

```
gc: done, 595 unreachable, 0 uncollectable, 0.0005s elapsed
gc: collecting generation 2...
gc: objects in each generation: 0 0 3051
gc: objects in permanent generation: 0
gc: done, 151 unreachable, 0 uncollectable, 0.0002s elapsed
```

GC internal structures: gc_runtime_state

Struct describing the current runtime status of the generational garbage collection

- long_lived_total
 number of objects that survived the last full collection
- long_lived_pending number of objects that survived all non-full collection

N.B. A *full collection* is a collection on all generations

To further limit the overhead, the generational gc starts a full collections only if long_lived_pending > long_lived_total / 4

```
struct _gc_runtime_state {
    ...
    struct gc_generation generations[NUM_GENERATIONS];
    PyGC_Head *generation0;
    struct gc_generation permanent_generation;
    struct gc_generation_stats generation_stats[NUM_GENERATIONS];
    ...
    Py_ssize_t long_lived_total;
    Py_ssize_t long_lived_pending;
};
```

More on that permanent_generation later: hold your horses! :-)

Generational GC lifecycle

GC lifecycle

When an object with Py_TPFLAGS_HAVE_GC flag is allocated, two things happen:

- 1. The allocation may start a gc collection cycle
- 2. The gc starts to track the newly allocated object

```
PyObject *
PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)
{
    PyObject *obj;
    ...
    if (PyType_IS_GC(type))
        obj = _PyObject_GC_Malloc(size);
    ...
    if (PyType_IS_GC(type))
        _PyObject_GC_TRACK(obj);
    return obj;
}
```

PyObject allocation

The allocation for the gc tracked objects:

- 1. adds the useful info for the generational gc to the object itself
- 2. update the stats about generations lists
- 3. if needed, starts a collection cycle calling collect_generations (more on this later)

```
static PyObject *
_PyObject_GC_Alloc(int use_calloc, size_t basicsize)
    PyObject *op;
    PyGC Head *q;
    size t size;
    size = sizeof(PyGC_Head) + basicsize;
    . . .
    g = (PyGC_Head *)PyObject_Malloc(size);
    q -> qc next = 0;
    g->_gc_prev=0;
    // ... update gc stats and triggers a gc collection
    op = FROM\_GC(g);
    return op;
```

A new object is tracked

The newly allocated object is inserted into the generation 0 to be scanned by the cycle detection algorithm

Inner details of the collection process

collect_generations

- find the oldest generation where the count exceeds the threshold
- collect objects from that generation and from all younger generations
- in case of use full collections apply the heuristic on long_lived_pending and long_lived_total values

```
static Py_ssize_t
collect_generations(void)
   int i:
   Py ssize t n = 0;
   for (i = NUM_GENERATIONS-1; i >= 0; i--) {
        if (_PyRuntime.gc.generations[i].count >
            PyRuntime.gc.generations[i].threshold) {
            if (i == NUM GENERATIONS - 1
                && _PyRuntime.gc.long_lived_pending <
                PyRuntime.gc.long lived total / 4)
                continue:
            n = collect with callback(i);
            break;
   return n;
```

gc module workhorse: the collect function

```
update_refs()subtract_refs()move_unreachable()check_garbage() and delete_garbage()
```

```
static Py_ssize_t
collect(int generation, Py_ssize_t *n_collected, Py_ssize_t *n_uncollectable,
        int nofail)
    /* merge younger generations with one we are currently collecting */
    for (i = 0; i < generation; i++) {</pre>
        gc list merge(GEN HEAD(i), GEN HEAD(generation));
     * Using ob_refcnt and gc_refs, calculate which objects in the
     * container set are reachable from outside the set.
    update_refs(young); // gc_prev is used for gc_refs
    subtract refs(young);
```

gc module workhorse: the collect function

```
. . .
/* Leave everything reachable from outside young in young, and move
 * everything else (in young) to unreachable.
gc list init(&unreachable);
move unreachable(young, &unreachable); // gc prev is pointer again
/* Move reachable objects to next generation. */
if (young != old) {
    if (generation == NUM GENERATIONS - 2) {
        PyRuntime.gc.long lived pending += gc list size(young);
    gc list merge(young, old);
if (check_garbage(&unreachable)) { // clear PREV_MASK_COLLECTING here
    gc list merge(&unreachable, old);
else {
     * Call tp clear on objects in the unreachable set. This will cause
     * the reference cycles to be broken.
     */
    delete garbage(&unreachable, old);
}
```

Cycle detection algorithm: the 30k foot view

To break reference cycles, the algorithm acts this way

- iterate over all objects in the young list
- for each object, traverse all its reference, and for each of these, decrement by one the gc_refs field of the referenced object

Cycle detection algorithm: update_refs

for each container object tracked by the gc:

- copy ob_refcnt into _gc_prev
- set PREV_MASK_COLLECTING flag to signal that gc is in progress for the object

```
static void
update_refs(PyGC_Head *containers)
{
    PyGC_Head *gc = GC_NEXT(containers);
    for (; gc != containers; gc = GC_NEXT(gc)) {
        gc_reset_refs(gc, Py_REFCNT(FROM_GC(gc)));
        ...
    }
}
```

Cycle detection algorithm: subtract_refs

for each container object tracked by the gc:

• use the *visitor pattern* to traverse the container and visit each referenced object

An example traversal for the list type:

```
static int list_traverse(PyListObject *o, visitproc visit, void *arg)
{
    Py_ssize_t i;
    for (i = Py_SIZE(o); --i >= 0; )
        Py_VISIT(o->ob_item[i]);
    return 0;
}
```

visit_decref: the subtract_refs visitor function

If the object is GC tracked and it belongs to the generation currently under collection, we decrement its saved reference count

When the traversal is complete for all objs, in young list we'll end up with two kind of objects:

- objs with reference count > 0
 these objs are surely reachable from outside the young list, so they won't be garbage collected
- objs with reference count == 0 these objects **may** be unreachable from outside, so they are now eligible to be garbage collected

Quick Quiz #5: still reachable objs

Can you figure out why some objects with reference count == 0 may still end up as reachable?

Quick Quiz #5: still reachable objs

Can you figure out why some objects with reference count == 0 may still end up as reachable?

answer

The object can be referenced by another object that belong to the same generation, but with a reference count > 0. Since this object is still reachable, the first one is reachable as well!

Take-home message

We'll know which objs can be collected only after a full scan of the young list

Cycle detection algorithm: move_unreachable

- move all objs with reference count == 0 to the unreachable list and set the NEXT MASK UNREACHABLE
- leave all reachable objs in young list, clearing the PREV_MASK_COLLECTING flag
 traverse all objs reachable from this object to mark them reachable as well
- restore _gc_prev as a pointer so that young and unreachable will be both doubly linked

```
static void move unreachable(PyGC Head *young, PyGC Head *unreachable)
   while (gc != young) {
        if (gc_get_refs(gc)) {
            PyObject *op = FROM GC(qc);
            traverseproc traverse = Py TYPE(op)->tp traverse;
            (void) traverse(op, (visitproc)visit reachable, (void *)young);
            // gc is not COLLECTING state after here.
            gc clear collecting(gc);
        else {
            // Move gc to unreachable.
            // Set NEXT MASK UNREACHABLE flag
        gc = (PyGC Head*)prev-> gc next;
```

Cycle detection algorithm: check_garbage

walk the collectable list and check that they are really unreachable

Why this, again? Because some objs could have been *resurrected* by a finalizer!

Thanks to PEP 442, since CPython 3.4, the generational gc can safely support finalizers:

- CPython scans the unreachable list to execute, when set, all object finalizers
- As a side effect, a finalizer can *resurrect* one or more object inside the unreachable list
- If that's the case, the unreachable list is merged with the older generation, as it is considered to have survived the collection process

delete_garbage

- break reference cycles by calling the appropriate clear function of the container.
- when ob_refcnt falls to 0, the object memory is finally released

```
static void delete_garbage(PyGC_Head *collectable, PyGC_Head *old)
   while (!gc_list_is_empty(collectable)) {
        PyGC_Head *gc = GC_NEXT(collectable);
        PyObject *op = FROM GC(qc);
        if ((clear = Py_TYPE(op)->tp_clear) != NULL) {
            Py_INCREF(op);
            (void) clear(op);
            Py_DECREF(op);
```

Feel confused?

If you feel confused by now... well, you're not alone!

Just read the comment on top of delete_garbage:-)

```
/*

* Break reference cycles by clearing the containers involved. This

* is tricky business as the lists can be changing and we don't

* know which objects may be freed. It is possible I screwed

* something up here.

*/
```

Garbage collection is hard, indeed.

Generational gc final performance notes

CPython generational garbage collection is a **stop-the-world** collector: during the entire collection process the program is not making progress

Despite this, the overall performance are acceptable for a general purpose implementation like CPython, due to the following reasons:

- Reference counting plays nicely with generational garbage collector every deallocation done by the reference counting decreases the objects in a generation, delaying the overcoming of the threshold
- The generations make the GC **incremental**The generations "segment" the memory, avoiding an entire heap scan every time the gc kicks in
- CPython limits full collections with a further heuristic
 As we seen, full collections starts only if the number of objects waiting for a full collection exceeds 25% of the objects that survived the last full collection

Garbage Collection in real life: an Instagram story

Linux Copy-on-Write

It is a kernel optimization to avoid unnecessary memory copy

- you have a process that owns a memory page
- that process forks a child process, this one will share the same memory page, marked as read-only
- when the child process tries to write to that page, it gets a page fault
- the kernel then duplicates the page before restarting the write

As a result, the memory page is copied by the kernel only when needed

Instagram tech stack

Python + Django + uWSGI

uWSGI allows a multi processing model based on fork and leverage the CoW relying on master process initialization

Linux CoW + uWSGI + Python gc

Do you remember the PyGC_Head struct we saw earlier?

```
/* GC information is stored BEFORE the object structure. */
typedef struct {
    uintptr_t _gc_next;
    uintptr_t _gc_prev;
} PyGC_Head;
```

The collect function uses _gc_prev to store a copy of the ob_refcnt for each container object, and run its cycle detection algorithm

Whenever a gc collection starts after a fork, the algorithm causes **a lot** of memory writes, thus a lot of page faults and, finally, a lot of memory copying after uWSGI fork!

first attempt: disable GC

gc.set_threshold(0)

Pros

- each process now shares 100 MB more than before
- CPU utilization higher than 10% due to reduced page faults

Cons

• 600 MB leaked memory with 3.000 requests

Unfortunately, it seems that writing reference cycles free code is not so easy for complex application

The growing leaked memory forced them to restart the server periodically, washing out the performance improvements gained after disabling gc

second attempt: gc_freeze

Objective:

- do not poke objects allocated before fork (objects in parent process)
- continue to collect all objects allocated after fork (objects in child processes)

Zekun Li, a sw eng from Instagram, contributed a patch to Python 3.7 to introduce gc_freeze

```
static PyObject * gc_freeze_impl(PyObject *module)
{
    for (int i = 0; i < NUM_GENERATIONS; ++i) {
        gc_list_merge(GEN_HEAD(i), &_PyRuntime.gc.permanent_generation.head);
        _PyRuntime.gc.generations[i].count = 0;
    }
    Py_RETURN_NONE;
}</pre>
```

That's what that permanent_generation is for: it holds objects *hidden* from the garbage collection process!

for further details, see Zekun Li's talk at Pycon 2018

PyPy garbage collection

What about PyPy?

PyPy does not use reference counting, but relies entirely on a *generational* stop-the-world garbage collector

The collections are divided into two categories:

- minor collections, regarding a limited number of newly allocated objects
- major collections, regarding all the other objects in the heap

major collections are the ones that cause longer GC pauses

incminimark

To limit the extension of these pauses, the major collections are splitted into pieces, to be executed **incrementally**. That's why the PyPy garbage collector has been called **incrinimark**.

Each gc piece (be it a mark or a sweep one) is executed after a minor collection, until the major collection process is complete.

There is one problem, though...

To limit the extension of these pauses, the major collections are splitted into pieces, to be executed **incrementally**. That's why the PyPy garbage collector has been called **incrinimark**.

Each gc piece (be it a mark or a sweep one) is executed after a minor collection, until the major collection process is complete.

There is one problem, though...

Since the collection process is splitted, the program now runs between the steps, potentially changing the references to the objects

Each gc piece (be it a mark or a sweep one) is executed after a minor collection, until the major collection process is complete.

There is one problem, though...

Since the collection process is splitted, the program now runs between the steps, potentially changing the references to the objects

How this can be solved?

Marking and sweeping

Regarding the sweep phase, unreachable objects will surely remain as such, so no issues arise

The marking phase is what is really causing troubles

To understand why we need to further inspect the inner details of the marking algorithm

In an incremental GC, we define three types of object sets:

In an incremental GC, we define three types of object sets:

- The **white** set
 It contains objects that are candidate to be collected
- The **black** set
 It contains all objects that are reachable and that do not have references
 to objects in the white set
- The **grey** set It contains all objects reachable, but still not entirely scanned for references to white objects

In an incremental GC, we define three types of object sets:

- The **white** set
 It contains objects that are candidate to be collected
- The black set
 It contains all objects that are reachable and that do not have references
 to objects in the white set
- The **grey** set
 It contains all objects reachable, but still not entirely scanned for references to white objects

During the **tri-color** marking phase, objects:

- start as white at the beginning
- become grey when they are found to be alive
- finally become black when all their references have been traversed

In an incremental GC, we define three types of object sets:

- The **white** set
 It contains objects that are candidate to be collected
- The black set
 It contains all objects that are reachable and that do not have references
 to objects in the white set
- The **grey** set
 It contains all objects reachable, but still not entirely scanned for references to white objects

During the **tri-color** marking phase, objects:

- start as white at the beginning
- become grey when they are found to be alive
- finally become black when all their references have been traversed

In other words, the coloring of an object follows this order:

white \rightarrow grey \rightarrow black

Tri-color marking invariant

Note that the described algorithm must hold the **tri-color inviariant** to work properly:

at any moment, no black objects should reference white objects

Otherwise, the white object would result as reachable through the reference inside the black object

Tri-color marking invariant

Note that the described algorithm must hold the **tri-color inviariant** to work properly:

at any moment, no black objects should reference white objects

Otherwise, the white object would result as reachable through the reference inside the black object

But since our program is running between the incremental marking steps, it may modify an already scanned object (a black one) to point to a temporarily unreachable object (a white one)!!!

Write barrier

The PyPy GC solves this problem introducing a write barrier

The write barrier simply keeps track of all objects being modified, to enqueue them for further marking

In particular, this kind of write barrier is a **backward write barrier**, since it colors the modified objects from black to grey, the opposite of the usual direction

Write barrier

The PyPy GC solves this problem introducing a write barrier

The write barrier simply keeps track of all objects being modified, to enqueue them for further marking

In particular, this kind of write barrier is a **backward write barrier**, since it colors the modified objects from black to grey, the opposite of the usual direction

N.B. the write barrier introduces a performance overhead due to the additional check while modifying any reference.

incminimark performance notes

incminimark uses a classical stop-the-world approach, but it *spreads* the gc work in incremental phases, to bound the introduced latency

The typical introduced latency is ~20-30 ms

incminimark performance notes

incminimark uses a classical stop-the-world approach, but it *spreads* the gc work in incremental phases, to bound the introduced latency

The typical introduced latency is ~20-30 ms

When having a predictable latency is a major constraint, PyPy allows to switch to a **semi-manual GC management**, in order to move the long GC pauses where feasible

The typical introduced latency is ~20-30 ms

When having a predictable latency is a major constraint, PyPy allows to switch to a **semi-manual GC management**, in order to move the long GC pauses where feasible

Two new features have been introduced in PyPy v7.0.0:

- gc.disable() to totally disable the major collections
- gc.collect_step() to manually run a single step of the major collection process

Go garbage collection

What about Go?

The gc used by Go is a **concurrent**, **tri-color**, **mark & sweep garbage collector**, strongly optimized for low latency performance

Differently from PyPy and CPython, Go gc is not generational

Google's engineers considered a generational approach, but finally gave up because:

The write barrier was fast but it simply wasn't fast enough

- Rick Hudson -

Concurrent garbage collection

The current algorithm does more work than a generational one, but can be executed (mostly) **concurrently** to the goroutines that modify the references.

This kind of architecture allowed Go to fulfill the (impressive) *Service Level Objective* of ~500 microseconds **Stop The World** pause per GC cycle

Still curious?

If you want to know more about Go garbage collection...
